1 Introduction

1.1 Rationale

Changes in Earth's forest cover impact the cycling of water, energy, carbon and other nutrients, as well as the ability of ecosystems to support biodiversity and human economies. Knowledge of the patterns and rates of forest-cover change is critical to understand the causes and effects of land-use change (Band 1993; Lal 1995; Houghton 1998; Pandey 2002) and to manage ecosystems sustainably. A number of national and international programs have called for routine monitoring of global forest changes, including the Global Observation for Forest and Land Cover Dynamics (GOFC-GOLD) (Skole *et al.* 1998; Townshend *et al.* 2004), Global Climate Observing System (GCOS 2004), and the U.S. Global Change Research Program (USGCRP 1999). An examination of the societal benefits defined by the Group on Earth Observations and the Strategic US Integrated Earth Observation System revealed that resolutions to all of these issues are dependent on regular and reliable land cover change monitoring (Townshend & Brady 2006).

Coarsely scaled measurements of Earth's forest cover have been produced at regional and national extents (Skole and Tucker 1993, Tucker and Townshend 2000, Steininger et al. 2001, DeFries et al. 2002, Zhang et al. 2005, Huang et al. 2007). However, most of these representations are static; and although a substantial proportion of change has been shown to occur at resolutions below 250 m (Townshend & Justice 1988), global assessments of forest cover and its changes at high-resolution are still in nascent stages of development while local and regional products (e.g., Lepers et al. 2005) lack consistency and comparability. Relying on national inputs and sampled remotely sensed data, the United Nations Food and Agriculture Organization (FAO) Forest Resource Assessment (FRA) carried out limited Landsat-based sampling of change detection to assist the estimation of global tropical forest change rates for 1990-2000 (FAO 2001). However, these sample-based assessments provide inadequate quantitative information on the distribution of change (Matthews and Grainger 2002, DeFries et al., 2002).

The NASA Earth Science Data Record (ESDR) of Global Forest Cover (GFC) provides global forest cover and change (FCC) records at fine (30-m) and moderate- (250-m) spatial resolutions. Requirements for such products are specified in many documents, including the *ESDR Community White Paper on Land Cover/Land Change* (Masek et al. 2006a) and the Global Observations of Forest Cover/Land-Cover Dynamics (GOFC-GOLD) Fine-Resolution design documents (Skole *et al.* 1998, Townshend *et al.* 2004). Landsat-class resolutions are essential for detecting fine-scale changes, particularly those resulting from local anthropogenic factors.

1.2 Objective

Although the temporal span and resolution have undergone subsequent improvements, the original objective of this project was to provide a multi-temporal forest-cover Earth Science Data Record (ESDR) at global extent and fine- (i.e., 30-m, "Landsat-") and moderate- (i.e., MODIS-) resolution. This record includes:

3

- Global, sub-hectare resolution estimates of surface reflectance for three epochs: 1990, 2000, and 2005;

- Fine-resolution forest cover change (FCC) estimates between the four epochs;

- Fragmentation indices derived from the fine-resolution FCC products;

- Subsets of the above products for world protected areas and surrounding buffer zones.

1.3 Approach

Global, spatially and temporally comprehensive forest-cover change Earth Science Data Records were inferred from high- (30-m) and moderate- (250-m) resolution satellite data. At 30-m spatial resolution, forest cover and changes in and between 1990, 2000, and 2005 were mapped using enhanced Global Land Survey (GLS+) data sets, supplemented with additional images where and when the GLS data were incomplete or inadequate for analysis (Tucker et al. 2004, Gutman et al. 2008, Channan et al. 2015). This effort also included production of surface reflectance ESDRs at 30-m resolution for 1990, 2000, and 2005, as well as fragmentation products based on the FCC records. (Note that the years 1990, 2000, and 2005 for all fine-resolution data sets refer to nominal years throughout this proposal, but the actual acquisition year of the GLS+ data set varies from place to place due to cloud cover and image availability.)

The fine-resolution ESDRs were produced using algorithms that have been implemented or are now implemented in the Landsat Ecosystem Disturbance Adaptive Processing System (LEDAPS), which was developed through previous NASA projects and includes algorithms for geometric orthorectification, radiometric normalization, and data quality screening. Atmospherically corrected surface reflectance, which is the basis for many other ESDRs and analyses, was generated as an intermediate product. For each year from 2000 to 2005, an enhanced moderate-resolution change product was generated as a secondary record of forest-cover change. We also generated products to quantify and monitor fragmentation.

Efforts were restricted to mapping per-pixel gains and losses of forest cover between the epochs at fine spatial resolution and between years for moderate spatial resolution. Also, we restricted our definition of FCC exclusively to changes in forest *cover* and not to any change in the type of forest land use (cf. FRA 2000). Even within forest cover *per se*, there are many other types of changes—e.g., selective logging—that are also important for many science and land-management applications (e.g. Muchoney & Haack 1994, Olsson 1994; Asner et al. 2005), but a global analysis of these is not yet feasible.

Like any ESDR, the data produced contain uncertainty, but this 15-year record represents a major advance in our understanding of Earth's changing forest cover. In processing the fine- and moderate-resolution data sets, we ensured that the data provide coverage of the greatest extent possible and are internally consistent and that errors and uncertainty are thoroughly characterized.

4

1.4   Significance

These Earth Science Data records provide the first and only consistent, global record of forest cover changes documenting the period from 1990 to 2005, and they enable the first comprehensive assessment of Earth's forest cover at a scale appropriate to recent changes. The data also provide the basis for understanding impacts of forest change on the Earth system, including carbon budgets and the hydrological cycle. The fine-resolution and global extent of the fragmentation products support habitat analyses and other ecological studies at scales ranging from local to global, which is particularly valuable to natural resource managers, especially those responsible for conserving biodiversity (Dudley et al. 2005; Hilli & Kuitunen 2005). The protected-area subsets of the forest change and fragmentation records allow assessment of local conservation effects as well as the broader effectiveness of international environmental and biodiversity agreements. The moderate-resolution products are of particular value to various modeling communities, especially those concerned with regional to global carbon modeling (Ojima & Galvin 1994, DeFries et al. 1999) and regional hydrological modeling (Band 1993, Sahin & Hall 1996, Bounoua et al., 2002). Completion of this project satisfies key components of the GOFC-GOLD requirements for fine-resolution products (Skole et al. 1997, Townshend et al. 2004) and forms a contributory activity to GOFC-GOLD through its Land Cover Implementation Team.

2   Primary data inputs

2.1   Landsat images

2.1.1   Enhanced Global Land Survey

The primary data sources for generating the fine-resolution ESDRs were the GLS Landsat image datasets centered around 1990, 2000, and 2005. The GLS is a partnership between USGS and NASA, in support of the U.S. Climate Change Science Program and the NASA Land-Cover and Land-use Change (LCLUC) Program. Building on the existing GeoCover dataset developed for the 1970s, 1990, and 2000 (Tucker et al. 2004), the GLS was selected to provide wall-to-wall, orthorectified, cloud free Landsat coverage of Earth's land area at 30-meter resolution in nominal "epochs" of 1990, 2000, and 2005 (Franks et al. 2009, Gutman et al. 2008). The GLS was intended to provide one clear-view image acquired during the peak growing season of each epoch for each World Reference System (WRS) scene. The 1990 epoch ranges from 1984 to 1997 and is composed of 7,375 Landsat-5 Thematic Mapper (TM) images from 1984 to 1997. The GLS 2000 is composed of 8,756 Landsat-7 Enhanced Thematic Mapper Plus (ETM+) images from 1999 to 2002. The GLS 2005 is composed of 7,284 gap-filled Landsat-7 images and 2,424 Landsat-5 TM images acquired between 2003 and 2008. In many cases, however, images had to be selected with a date outside this range, mostly due to lack of cloud-free images during the growing season (Franks et al. 2009, Gutman et al. 2008, Channan et al. 2015). Because images have been selected from somewhat different dates, there are variations in phenology which account for the patchiness of image mosaics in some locations (Kim et al. 2011; Townshend et al. 2012).

171   The original GLS data set did not fully cover Earth's terrestrial surface in all epochs; gaps
172   were filled to the degree possible with newly available images (Figure 1). A major hole over
173   northern South America in 1975 was filled using Landsat images from the Brazilian National
174   Institute for Space Research (INPE) orthorectified using our own modules. However, no data
175   exist to fill an expansive coverage gap over central and eastern Siberia in the 1990 epoch.
176   Smaller, isolated holes also persist where coverage is missing in one or several adjacent WRS
177   tiles for individual epochs; we obtained the best available Landsat images to fill these gaps.
178   Finally, GLS images acquired near or during the leaf-off season, which are not suitable for
179   forest cover change analysis, were replaced with images acquired during the local "leaf-on"
180   growing season to use in our forest cover change analysis, pending availability (Kim et al.
181   2011, Channan et al. 2015).

2.1.2   Phenological selection

183   A challenge in using GLS data sets for analysis is that many of the GLS images were acquired
184   near or during leaf-off seasons. Because the spectral differences between leaf-on and leaf-
185   off deciduous forests can be great, automated FCC analysis based on leaf-off images can
186   result in widespread, erroneous changes. Prior to classification and forest change analysis,
187   each Landsat image was evaluated to determine its phenological suitability for forest-cover-
188   change analysis. We used the NDVI temporal profiles calculated using the GIMMS AVHRR
189   and MODIS data record (Tucker et al., 2005) to determine whether an image was acquired
190   near or during leaf-off seasons. The GLS 1990, 2000, and 2005 images were evaluated using
191   the GIMMS record directly.

192

193

194   **Figure 1. GLS image holdings, including 1975 MSS amendments acquired by the GLCF from INPE.**

6

195

2.1.3 Orthorectification

Many non-GLS Landsat images were needed to supplement the GLS dataset to produce the fine-resolution ESDR products. Many of these non-GLS images were not orthorectified and might therefore have contained significant geolocation errors. We developed and implemented an orthorectification algorithm in the LEDAPS software that automatically orthorectifies a Landsat image to match the GLS data set (Gao et al. 2009). The module was used to orthorectify over 500 images in North America, ~30 images in Madagascar, and ~20 images in Africa, as well several SLC-off ETM+ images. During extensive validation, residual misregistration errors in the orthorectified products were found to be less than 1 pixel.

2.2 Digital Elevation Model: ASTER GDEM (v2.0)

We used the Global Digital Elevation Model, version 2.0 (GDEM v2.0) as an ancillary layer in many analyses. Produced from images acquired by the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) the GDEM dataset was jointly released by the Ministry of Economy, Trade, and Industry (METI) of Japan and NASA. The first and second versions of the ASTER GDEM were released in June 2009 and October 2011 respectively. The 30-meter resolution ASTER GDEM was generated using stereo-pair images collected by the ASTER instrument onboard the Terra satellite. The dataset is distributed in GeoTIFF format, spanning from 83S to 83N.

2.3 MODIS VCF Tree Cover Layer

The MODerate-resolution Imaging Spectroradiometer (MODIS) Vegetation Continuous Fields (VCF) Tree Cover dataset, Version 5, was produced at 250-m resolution globally from 2000 to 2010 (DiMiceli et al 2011). In contrast to methods based on linear mixture models (e.g., DeFries et al. 1999, Asner et al. 2005), the MODIS VCF is based on a flexible regression tree algorithm, which is more capable of incorporating empirical information to improve correlation of estimates to measured tree cover. Although the MODIS Tree Cover VCF has been used for a wide range of continental- to global-scale assessments, many land cover changes occur in patches beneath its 250-m resolution (Townshend and Justice 1988). Higher-resolution continuous-field datasets had been generated for limited areas based on Landsat data (e.g., Homer et al. 2004), but there were currently no global datasets representing tree cover at resolutions finer than that of the MODIS sensor.

The spatial and thematic scale of the MODIS VCF and other continuous-field datasets (e.g., Asner et al. 2005 have made reference data difficult to acquire, and so quantitative error estimates of these datasets are quite limited. Hansen et al. (2002) provided the first *de facto*—although not independent—estimates of MODIS VCF accuracy by comparing an experimental version of the dataset to the Landsat data used to train the generating model. Later, White et al. (2005) compared the MODIS VCF Version 1 to independently gathered field data across the arid southwestern US, and Montesano et al. (2009) validated the Version-4 MODIS VCF against independent reference data derived from photo-interpreted high-resolution images across the boreal-taiga ecotone. Also, Heiskanen et al. (2008) and Song et al. (2011) compared the MODIS VCF to other remotely sensed global datasets.

Global Land Cover Facility
www.landcover.org

236 Across all biomes and types of reference data, these independent assessments found that
237 saturation of the optical signal, phenological noise, and confusion with dense herbaceous
238 vegetation led to errors in the MODIS VCF between 10-31% Root-Mean-Squared Error
239 (RMSE), over-estimation in areas of low cover, and under-estimation in areas of high cover.

3 Primary data products

3.1 High- (30-m) resolution Earth Science Data Records

3.1.1 Surface Reflectance

3.1.1.1 Introduction

244 Reflectance is defined as the fraction of incident radiance within a specified interval, or
245 band, of the electromagnetic spectrum that is reflected (i.e., neither absorbed nor from a
246 target. Directional surface reflectance is further specified as the ratio of the radiance
247 reflected from a surface to the incident radiance incoming from a direct source of
248 illumination in a given infinitesimal solid angle. Estimated by atmospheric correction of
249 satellite images, directional reflectance ideally decouples the surface properties from the
250 atmospheric signal, thus representing the value that would be measured by an ideal sensor
251 held just above the Earth's surface at a given solar and viewing geometry and without any
252 atmospheric effects.

253 Directional surface reflectance is the most basic remotely sensed surface parameter in the
254 solar- reflective wavelengths and therefore provides the primary input for essentially all
255 higher-level surface geophysical parameters, including vegetation indices, albedo, Leaf Area
256 Index (LAI), Fraction of absorbed Photosynthetically Active Radiation (FPAR), burned area,
257 land cover and land cover change. Directional surface reflectance is also directly used in
258 various applications to visually or quantitatively detect and monitor changes on the Earth's
259 surface. Because they enable other comparisons among data imaged under various
260 illumination and atmospheric conditions, reflectance data products have value
261 independently of their utility for monitoring forest cover change. For example, the ESDR
262 Community White Paper on Surface Reflectance (Vermote et al., 2006) notes that validation
263 of global reflectance data sets from AVHRR, MODIS, and VIIRS will need to rely on
264 reflectance products derived from high-resolution sensors.

265 Nearly half of the original GLS-1990 dataset did not have correct radiometric gain and bias
266 coefficients at the time of data acquisition; thus atmospheric correction and conversion to
267 surface reflectance were not possible (Chander et al. 2003, 2009; Townshend et al. 2012).
268 These un-calibrated GLS images were replaced after the original GLS compilation with
269 substitutes from the updated USGS archive within the epoch wherever possible (Figure 1).
270 To perform the selection of replacement imagery while minimizing phenological or
271 atmospheric noise, a tool was constructed to query the USGS Global Visualization Viewer
272 (GloVis) database (glovis.usgs.gov/) for appropriate images based on phenological time
273 series of Normalized Difference Vegetation Index (NDVI) from the MODerate-resolution
274 Spectroradiometer (MODIS) (Kim et al. 2011; Townshend et al. 2012).

Global Land Cover Facility
www.landcover.org

275 Each image of this enhanced GLS dataset was then atmospherically corrected to surface
276 reflectance using the Landsat Ecosystem Disturbance Adaptive Processing System (LEDAPS)
277 (Masek et al. 2006b). Atmospheric inputs and parameterization of LEDAPS are described by
278 Feng et al. (2013). The surface reflectance data set from the enhanced version of GLS-1990 is
279 available from the Global Land Cover Facility (www.landcover.org) and use of these data is
280 strongly recommended for studies based on the GLS-1990 data. Clouds were identified in a
281 spectral-temperature space (Huang et al. 2010) and removed from subsequent analysis. This
282 "aggressive" cloud-detection algorithm's low rate of omission error makes it suitable for
283 masking pixels from forest-cover change analysis. Cloud shadows were identified by
284 projecting cloud masks onto a digital elevation model through solar geometry at the time of
285 image acquisition (Huang et al. 2010) and were also removed from analysis.

286 ### *3.1.1.2   Algorithm*

287 #### 3.1.1.2.1   Radiometric calibration and estimation of top-of-atmosphere reflectance
288 The Landsat-7 ETM+ instrument has been carefully calibrated and monitored since launch in
289 1999, and the calibration has been stable since shortly after launch (Markham et al. 2003).
290 The Landsat-5 calibration history has recently been updated (Chander & Markham 2003,
291 Chander et al. 2009) and is compatible with subsequent Landsat-7 ETM+ data. LEDAPS uses
292 updated calibration histories to convert 8-bit quantized Landsat data to at-sensor radiance
293 and then to top-of-atmosphere (TOA) reflectance using solar geometry and instrument band
294 pass.

295 #### 3.1.1.2.2   Atmospheric correction to estimate surface reflectance
296 Atmospheric correction seeks to estimate surface reflectance by compensating for the
297 scattering and absorption of radiance by atmospheric constituents. In practice, atmospheric
298 correction is typically achieved by inverting a highly parameterized model of atmospheric
299 radiative transfer coupled to a surface reflectance model. For speed and simplicity, the
300 reflecting surface is often assumed to be Lambertian. Atmospheric radiative transfer
301 modeling is relatively mature, and so several methods may be used to model the
302 surface/atmosphere interaction (e.g., Successive Order of Scattering, Doubling adding). The
303 main challenge to the operational implementation of these models lies in the assignment of
304 the atmospheric parameters and the *a priori* knowledge of the surface BRDF – strictly
305 necessary for a full inversion. Approaches to operationally retrieving the atmospheric
306 parameters have advanced considerably in the last 10 years as remote sensing instruments
307 capable of retrieving atmospheric properties (aerosol, ozone, water vapor, etc..) have been
308 put into operation. In the absence of operational retrievals, atmospheric climatology or
309 forecasted values can be applied, although product accuracy degrades considerably without
310 coincident atmospheric measurements. The determination of surface BRDF is currently
311 practical operationally only for satellite sensors with single-pass multi-angular capability,
312 such as MISR or POLDER. Thus, the uncertainty introduced by surface BRDF was assumed to
313 be constant inter-annually and to not have significant influence on analyses at this temporal
314 scale.

315 The atmospheric perturbation of the directional surface reflectance signal depends on the
316 type and characteristics of atmospheric particles interacting with the radiation. Atmospheric
317 gas molecules (N_2, O_2, O_3, H_2O, CO_2, etc.) scatter radiation according to Rayleigh's theory
318 (i.e., molecular scattering) and absorb radiation over the spectrum varying by species. These
319 specific scattering effects are governed by atmospheric pressure and the vertical
320 temperature profile. Aerosols (i.e., suspended particles ranging from about $10^{-3}\mu m$ to about
321 $20\mu m$) scatter and absorb radiation according to the Mie and Geometric Optics theories; the
322 former applies to aerosols with diameters on the order of the radiation's wavelength, and
323 the latter idealizes particles larger than the wavelength of radiation as individual spheres
324 with given real and imaginary refractive indices.

325 Atmospheric correction removes or reduces the effects of these atmospheric perturbations.
326 In an idealized case of a Lambertian surface (i.e., with angularly uniform reflectance) and in a
327 narrow spectral band (here referred to with the index [i]) outside of the main absorption
328 feature of water vapor, the top-of-atmosphere signal can be written as (Vermote et al.
329 1997):

330

331
$$\rho_{TOA}^i(\theta_s,\theta_v,\phi,A,\overbrace{\tau_A^i,\omega_0^i,P_A^i}^{Aer^i},U_{H_2O},U_{O_3}) = Tg_{OG}^i(m,A)Tg_{O_3}^i(m,U_{O_3})\left[\begin{array}{l}\rho_{atm}^i(\theta_s,\theta_v,\phi,A,Aer^i,U_{H_2O}) + \\ Tr_{atm}^i(\theta_s,\theta_v,A,Aer^i)\dfrac{\rho_s}{1-S_{atm}^i(A,Aer^i)\rho_s}Tg_{H_2O}^i(m,U_{U_{H_2O}})\end{array}\right], \quad (1)$$

332

333 where:

334 ρ_{TOA} is the reflectance at the top of the atmosphere;
335 Tg is the gaseous transmission by a gas species (g), e.g., water vapor (Tg_{H_2O}), ozone
336 (Tg_{O_3}), or other gases, Tg_{OG} (e.g. CO_2...);
337 ρ_{atm} is the atmosphere's intrinsic reflectance;
338 Tr_{atm} is the total atmospheric transmission (downward and upward);
339 S_{atm} is the atmosphere's spherical albedo;
340 A is the atmospheric pressure, which influences the number of molecules and the
341 concentration of absorbing gases in the radiation's path;
342 τ_A, ω_0 and P_A describe the aerosol properties and are spectrally dependent:
343 τ_a is the aerosol optical thickness;
344 ω_0 is the aerosol single scattering albedo;
345 P_A is the aerosol phase function;
346 U_{H_2O} is the integrated water vapor content;
347 U_{O_3} is the integrated ozone content;
348 m is the air-mass, computed as $1/\cos(\theta_s)+1/\cos(\theta_v)$; and
349 ρ_S is the surface reflectance to be retrieved.
350

351 The geometrical conditions are described by the solar zenith angle (θs), the viewing zenith
352 angle (θv), and by Φ, the difference between θs and θ_v. The effect of water vapor on the
353 intrinsic atmospheric reflectance is approximated as:

10

354

$$\rho_{atm}^i(\theta_s,\theta_v,\phi,A,Aer^i,U_{H_2O}) = \rho_R^i(\theta_s,\theta_v,\phi,A) +$$

$$\left(\rho_{R+Aer}^i(\theta_s,\theta_v,\phi,A,Aer^i) - \rho_R^i(\theta_s,\theta_v,\phi,A)\right)Tg_{H_2O}^i(m,\frac{U_{U_{H_2O}}}{2})$$

355 $$,\qquad (2)$$

356

357 where ρ_R represents the reflectance of the atmosphere due to Rayleigh scattering and ρ_{R+Aer}
358 represents the reflectance of the mixing molecules and aerosols. Accounting correctly for
359 mixing and coupling effects is important for achieving high accuracy in modeling the
360 atmospheric effect. Eqn. (2) conserves the correct computation of the coupling and assumes
361 that the water vapor is mixed with aerosol and that the molecular scattering is not affected
362 by water vapor absorption.

363 The transmission, intrinsic reflectance, and spherical albedo terms are computed using the
364 vector version of the 6S radiative transfer code (Kotchenova et al. 2006). Since the cost of
365 running 6S for each pixel would be prohibitive, 6S was run early in the process to generate a
366 look up table (LUT) accounting for pressure, water vapor, ozone, and geometrical conditions
367 over the whole scene for a range of aerosol optical thicknesses. The LUT was created for
368 each TM band and was used both in the aerosol retrieval process as well as in the correction
369 step at the end.

370 Ozone concentrations were derived from Total Ozone Mapping Spectrometer (TOMS) data
371 aboard the Nimbus-7, Meteor-3, and Earth Probe platforms. The gridded TOMS ozone
372 products are available since 1978 at a resolution of 1.25º longitude and 1.00º latitude from
373 the NASA GSFC Data Active Archive Center (DAAC). In cases where TOMS data were not
374 available (e.g., 1994–1996), NOAA's Tiros Operational Vertical Sounder (TOVS) ozone data
375 were used. Column water vapor was taken from NOAA National Centers for Environmental
376 Prediction (NCEP) reanalysis data available at a resolution of 2.5 by 2.5 degrees
377 (http://dss.ucar.edu/datasets/ds090.0/) over the Landsat era. Digital topography (1 km
378 GTopo30) and NCEP sea-level surface pressure data were used to adjust Rayleigh scattering
379 to local conditions.

380 Like other atmospheric correction schemes for MODIS and Landsat, the Dark, Dense
381 Vegetation (DDV) method (Kaufman et al. 1997; Remer et al. 2005) was used to infer aerosol
382 optical thickness (AOT) from each image. Based on the correlation between chlorophyll
383 absorption and bound water absorption, this method postulates a linear relation between
384 surface reflectance in the atmospherically insensitive shortwave-infrared (2.2 µm) and
385 surface reflectance in the affected visible bands. The method then uses this relation to
386 calculate surface reflectance for the visible bands and estimate aerosol optical thickness by
387 comparing the result to the TOA reflectance. For LEDAPS AOT estimation, each image was
388 averaged to 1-km resolution to suppress local heterogeneity, and candidate "dark targets" of
389 TOA reflectance were selected. For these targets, correlation was assumed only between the
390 blue (0.45–0.52) and SWIR (2.2µm) bands, such that water targets were excluded. The

11

391 specific relation was derived from an analysis of data from Aerosol Robotic Network
392 (AERONET) sites where AOT is measured directly. The calculated AOT in the blue
393 wavelengths was propagated across the spectrum using a continental aerosol model. A
394 "sanity check" for the aerosol was performed by analyzing the surface reflectance derived in
395 the red band for each 30-m pixel contained in the 1-km grid cell; if too many "unphysical"
396 values were found, the aerosol retrieval at this 1-km location was rejected. The valid aerosol
397 optical thicknesses at 1 km were interpolated spatially between the dark targets using a
398 spline algorithm. The interpolated AOT, ozone, atmospheric pressure, and water vapor were
399 supplied to the 6S radiative transfer algorithm, which then inverts TOA reflectance for
400 surface reflectance for each 30-m pixel.

401 As noted above, water targets were excluded from the aerosol retrieval. However,
402 interpolation of valid (i.e., land) aerosol targets occurs across the entire scene. Thus, the
403 surface reflectance of small lakes surrounded by land was likely to be reasonable, while the
404 reflectance of open ocean water (far from any valid aerosol target) was likely to be
405 problematic.

3.1.1.2.3 Cloud- and shadow- masking
407 Removing pixels contaminated by clouds and their shadows was necessary to avoid
408 erroneous retrieval of surface reflectance and false detection of forest-cover change.
409 LEDAPS implemented two cloud masks – a version of the Landsat Automated Cloud Cover
410 Assessment (ACCA) algorithm (Irish, 2000) and a more aggressive mask based on MODIS
411 spectral tests (Ackerman et al. 1998). Shadows were located from the latter using solar
412 geometry and an estimate of cloud height based on the temperature difference between
413 known cloudy pixels and NCEP surface temperature. A third cloud-masking algorithm has
414 been developed by Dr. Vermote through his USGS-funded Landsat Science Team project – "A
415 Surface Reflectance Standard Product for LDCM and Supporting Activities". Quality
416 Assessment codes for this algorithm are listed in Table 1. Finally, an automated cloud and
417 shadow masking algorithm has also been developed by Huang et al. (2010) as part of the
418 TDA-SVM algorithm.

3.1.1.3 Validation
420 Landsat surface reflectance products were validated in two ways. Internal aerosol optical
421 thickness (AOT) estimates retrieved by LEDAPS have been compared to measurements taken
422 at Aerosol Robotic Network (AERONET) observations (Masek et al. 2006b), and surface
423 reflectance was compared to simultaneously acquired MODIS daily reflectance and Nadir-
424 and BRDF-Adjusted Reflectance (NBAR) images (MOD09 and MOD43, respectively) (Feng et
425 al 2013). These paired validations provide an internal check on a driving parameter of the
426 LEDAPS algorithm (AOT), as well as a consistency check against the thoroughly calibrated
427 and validated MODIS product.

428

429 **Table 1. Quality flags produced by cloud masking, distributed in 16-bit Quality Assessment (QA) layer.**

Bit	meaning
0	Unused

1	Valid data (0=yes, 1=no)
2	Cloud identified by ACCA (1=cloudy, 0 = clear)
3	Unused
4	ACCA snow mask
5	DEM-based land mask (1=land, 0=water)
6	Dense, Dark Vegetation (DDV)
7	Unused
8	Internal cloud mask (1=cloudy, 0=clear)
9	Cloud shadow
10	Snow mask
11	Land/water mask based on spectral test

430

3.1.1.3.1   Comparison of retrieved AOT to AERONET measurements

432   Aerosol Robotic Network (AERONET) sites measure and record aerosol properties across the
433   globe, with records at some sites extending back to the early 1990's (Holben et al. 1998).
434   Aerosol optical thickness estimates from pixels processed through LEDAPS were compared
435   to coincident measurements from 21 of these AERONET sites (Table 2, Figure 2). All AOT
436   values reported are for the blue wavelengths. Results suggest reasonable agreement with
437   AERONET observations, and the discrepancies between LEDAPS and MODIS reflectance
438   products were generally within the uncertainty of the MODIS products themselves—the
439   greater of 0.5% absolute reflectance or 5% of the retrieved reflectance value. Spatial
440   patterns for the sites suggested that land cover type may influence the aerosol retrievals
441   (Figure 3), although this artifact was slight in comparison to the direct effect of reflectance
442   itself and therefore appears to have little impact on the retrieved surface reflectance values.

443

Figure 2. ETM+ AOT values regressed against simultaneous AERONET AOT values for the blue band.
Solid red line is the one-to-one line, dashed lines represent MODIS AOT uncertainties of (0.05+0.2*AOT).

451

452 **3.1.1.3.2 Operational Quality Assessment**

453 A second validation was based on MODIS surface reflectance estimates. With bands
454 corresponding to each of Landsat 7's solar-reflective bands (Table 3), the MODIS sensor
455 aboard the Terra platform follows the same orbit and crosses the equator roughly 30
456 minutes behind Landsat 7. MODIS surface reflectance data products (MOD09) have been
457 calibrated and validated comprehensively (Vermote et al. 2002, Kotchenova et al. 2006,
458 Vermote and Kotchenova 2008) and may be used as a reference to validate Landsat surface
459 reflectance products (Feng et al. 2012).

460 We developed an online tool for validating Landsat surface reflectance estimates against
461 coincident MODIS estimates and used it to validate the 2000- and 2005-epoch SR products.
462 Initial tests for WRS-2 scenes over eastern Africa showed strong agreement between
463 Landsat-7 ETM+ and MODIS surface reflectance products, with the majority of R^2 values
464 above 0.9 (Figure 4). Landsat scenes with R^2 values below 0.8 were inspected individually,
465 revealing explanations for the discrepancy. Of the poor quality images, one was corrupted
466 and others were either cloudy or dominated by ocean.

3.1.2   Tree Cover (2000 and 2005)

Spatio-temporal estimates of tree-canopy (or simply "tree") cover provide a biophysically relevant, sensible, and consistent basis for monitoring forest cover and change (Sexton et al. 2016). The following algorithm and its results have been peer-reviewed and are described by Sexton et al. (2013b).

3.1.2.1   Algorithm

3.1.2.1.1   Model

Tree cover (C) was estimated as a piecewise-linear function of surface reflectance and temperature:

$$C_{i,t} = f(X_{i,t}) + \varepsilon, \tag{3}$$

where X is a vector of surface reflectance and temperature estimates, ε is error in the estimates produced by $f()$ applied to X, subscript i denotes the pixel's location in space, indexed by pixel, and t refers to its location in time, indexed by year. Continuous measurements, such as percent cover and surface reflectance, are robust to changes in resolution (Gao et al. 2006, Feng et al. 2013); although the data were derived from Landsat; the model makes no specification of scale and thus may be calibrated and applied at arbitrary, even different, resolutions between those of Landsat (30 m) and MODIS (250 m).

To estimate tree cover at 30-m resolution in 2000 and 2005, MODIS-based, 250-m tree cover estimates were overlaid on rescaled Landsat surface reflectance layers in each year, and a joint sample of cover and reflectance variables was drawn to generate a training dataset for each Landsat scene in each epoch (Figure 5). (Throughout this section, we refer to the data used to estimate model parameters as "training" data, and we refer to data whose accuracy is assumed as "reference" data.)

The model was thus fit locally to each scene of the Landsat tiling system of WRS-2 in each epoch. The model was fit using the Cubist™ regression tree algorithm and applied using CubistSAM, an open-source parser for Cubist (Quinlan 1993). Except for an allowance for extrapolation within the range [0,100], our application of regression trees was standard (i.e., neither sample boosting or bagging nor ensemble "random forests" or "committee models" were employed). Cubist – as well as regression trees in general - has been found to provide accurate estimates of percent-scale land cover attributes in numerous studies (e.g., Sexton et al. 2006, 2013a). Because regression trees can over-fit the data and there are often few data points at the extremes of the range of the response variable (e.g., tree cover), Cubist gives an option for either estimating within the range of the response variable at each node (the default) or extrapolating within a specified range. To avoid over-fitting to the sometimes small samples at terminal nodes with extreme cover values, we allowed for extrapolation within the range of 0-100% tree cover. The fitted model was then applied to

512　the original, 30-m Landsat data in order to estimate tree cover at the Landsat spatial
513　resolution.

514

516　**Figure 5. Flowchart of tree-cover rescaling algorithm.**
517

518　3.1.2.1.2　Training data
519　"Training" tree-cover data for model fitting were derived primarily from the 250-m MODIS
520　VCF Tree Cover layer (DiMiceli et al. 2011) from 2000-2005. Random errors (i.e., those
521　which were not systematic, e.g., bias) were minimized by using the six-year median of cover
522　for each pixel. Land-cover changes between 2000 and 2005 were removed by calculating

17

523   the standard deviation of annual tree cover estimates for each pixel over that interval and
524   removing pixels in the top 10% of the distribution of standard deviations of each Landsat
525   scene. Because only six years of MODIS VCF data were available, we used the median, which
526   is a better representation of central tendency than the mean in small samples such as the six
527   values of cover from 2000-2005.

528   Pure (i.e., 0% or 100%) and near-pure pixels are rare in the MODIS data, and tree cover
529   tends to be over-estimated in areas of low cover, especially agricultural fields. To ameliorate
530   under-representation of low tree-cover in the training sample, we augmented the MODIS-
531   derived reference data with information from the Training Data Automation and Support
532   Vector Machines (TDA-SVM) automated classification algorithm (Huang et al. 2008) and the
533   MODIS Cropland Probability Layer (Pittman et al. 2010). Cropland Probability and Tree Cover
534   images were overlaid within each Landsat scene, and Landsat pixels with crop probability >
535   0.5 and tree cover < 50% were selected. This selection comprised Landsat pixels with either
536   crop or sparse vegetation cover. Within the selection, Landsat pixels identified by TDA-SVM
537   as "non-forest" in both 2000 and 2005 were assumed to be sparsely vegetated and were
538   labeled as 0% tree cover. The remaining (i.e., crop) pixels in the selection were ranked by
539   their NDVI values and divided into three sub-strata: high, medium, and low NDVI. Pixels
540   from each of these sub-strata were randomly sampled such that the maximum proportion of
541   Landsat "crop" pixels was the proportion of MODIS pixels within the scene whose crop
542   probability was > 60%. All of the sparsely vegetated pixels and the sample of crop pixels
543   were then pooled with the MODIS-based reference data to form an ensemble training
544   sample of tree cover and reflectance.

545   ### 3.1.2.2   Post-processing

546   3.1.2.2.1   Water mask
547   Surface-water bodies were masked from the tree and forest-cover & change data, and the
548   surface-water layer is a useful input to many other applications. The following algorithm is
549   described by Feng et al. (2015).

550   Water cover was defined as a state of the landcover domain c ∈ C, and its probability of
551   occurrence in each pixel was modeled as a function of reflectance and topographic
552   covariates (X):

553   P(c = "water"|X)   (4)

554   where f is a binary decision tree fit by the See5™ algorithm (Quinlan 1986, 1993). The
555   topographic covariates were elevation and slope derived from the ASTER GDEM (Tachikawa
556   2011), reflectance covariates were Landsat Band-5 (SWIR) surface reflectance, the
557   Normalized-Difference Water index (NDWI) (McFeeters 1996):

558

559   $NDWI = (\rho_G - \rho_{NIR})/(\rho_G + \rho_{NIR}))$,   (5)

560

18

561 and the Modified Normalized-Difference Water index (MNDWI) (Xu 2006):

563 $$MNDWI = (\rho_G - \rho_{SWIR1})/(\rho_G + \rho_{SWIR1})\,),\qquad\qquad(6)$$

565 to distinguish water from other cover types, as well as the Normalized Difference Vegetation
566 Index (NDVI) (Tucker et al. 2005)

568 $$NDVI = (\rho_{NIR} - \rho_R)/(\rho_{NIR} + \rho_R)\qquad\qquad(7)$$

570 to distinguishes water from vegetation specifically. The optimal threshold of each index for
571 separating water varies regionally and over time due to mixing and local similarities with
572 other cover types (Ji et al. 2009; Jiang et al. 2014).

573 Water was detected in each 30-m Landsat pixel with a classification-tree model (Quinlan
574 1986) parameterized through an automated, two-stage procedure. An initial, deductive
575 stage identified reference water pixels of varying certainty by comparing multi-spectral
576 water and topographic indices to coarse-resolution (MODIS) water estimates. This stage
577 leveraged prior knowledge with multiple sources of independent information to stratify the
578 decision space into regions of possible water with varying degrees of certainty. An inductive
579 stage then optimizes rules based on high-resolution estimates of surface reflectance,
580 brightness temperature, and terrain elevation.

581 The first stage of classification generates local reference data with varying levels of certainty.
582 The pixels, identified as water by multi-spectral indices, were compared with *a priori* water
583 pixels resampled from the 250-m resolution MODIS water mask to the spatial resolution and
584 extent of each Landsat image. This comparison resulted in four possible levels of certainty,
585 through which weights were assigned to each reference datum (Table 4).

586 Topographic, spectral, and brightness temperature variables were first stratified into generic
587 cover types: water, land, snow and ice, and cloud. A loose and a strict threshold—equaling -
588 0.1 and 0.1—were applied each to NDWI and MNDWI to distinguish water with low and high
589 certainty. Terrain shadows were identified as pixels with hill-shade value <150 (on a scale
590 from 0 to 255) and slope >20 degrees, as discussed in section 2.1.2.

591 Snow and ice show high reflectance values in the visible and NIR bands and low reflectance
592 in SWIR bands, leading to high MNDWI but low to moderate NDWI. A strict difference
593 threshold (0.7) was used to reduce confusion of water with snow and ice, and a criterion of
594 brightness temperature <1.5 ℃ was also included to further improve the discrimination:

595 $$MNDWI > NDWI + 0.7 \text{ and } \rho_6 < 1.5\,℃.\qquad\qquad(8)$$

596 **Table** 4**. Weights applied to observations in training ensemble of Landsat-based water mask.**

Data	Stratum	Agreement with MODIS water mask	Weight
Landsat indices	High certainty water	Agree	1.0
		Disagree	0.5
	Low certainty water	Agree	0.1
		Disagree	0.05
	Non-water		0.1
	Snow/ice		0.3
Terrain indices	Terrain shadow		0.3

597

598 3.1.2.2.2   Mosaicking
599 Redundancy among multiple images was leveraged to maximize certainty in each location
600 within each epoch. This is accomplished by a "best-pixel" compositing rule, taking the tree-
601 cover estimate with the lowest estimated uncertainty from those available.

602 For each location (x,y) in each epoch (t), there could be any number, k ∈ K= [1,2…n], of cover
603 and uncertainty estimate-pairs $(\hat{c}, \hat{\varepsilon})_{x,y,t,k}$. The "best-pixel" approach takes the least
604 uncertain estimate of cover, as well as its corresponding estimate of uncertainty:

605

606 $$(\hat{c}, \hat{\varepsilon})'_{x,y,t} = argmin_{\hat{\varepsilon}}(\hat{c}, \hat{\varepsilon})_{x,y,t,K}. \qquad (9)$$

607

608 For a static, continuous variable (e.g., tree cover), $\hat{\varepsilon}$ is quantified as the root-mean-square
609 error of the estimate. For a static, categorical variable (e.g., forest cover), $\hat{\varepsilon}$ is quantified as
610 the complement of the probability of class membership--i.e., $1-p(\hat{c})$.

611 This selection was applied up to twice for each (x,y,t) pixel: first if there were multiple
612 Landsat images available for a scene ("within-scene compositing") and second if multiple
613 WRS-2 scenes overlapped at that pixel location ("sidelap compositing"). Missing estimates in
614 any of the contributing images (due, e.g., to clouds, cloud- or terrain-shadows, or scan-line
615 gaps) were treated as having maximum uncertainty so that pixels were filled with clear-view
616 estimates wherever available.

617 *3.1.2.3   Validation*

618 3.1.2.3.1   Methods
619 The uncertainty of the tree-cover estimate in every pixel was assessed relative to the
620 training data by ten-fold cross-validation. Pixel-level uncertainty was quantified at each
621 terminal node of the regression tree and assigned to pixels identified with that node.
622 Because these pixel-level uncertainties were assessed only relative to their training data,
623 errors between the reference data and actual cover were not included at the pixel level. As
624 described in a later section, training (MODIS) and output estimates were compared to

20

625 approximately coincident measurements derived from small-footprint lidar measurements
626 in order to assess their accuracy relative to more direct measurements of actual cover. (We
627 use the term "measurement" to refer to lidar-derived values of cover – which are calculated
628 without statistical inference – and the more general "estimate" to refer to values derived
629 statistically from MODIS and Landsat images.) All comparisons were made at 250-m
630 resolution, using MODIS estimates from 2005 and Landsat estimates from the 2005 epoch.
631 Preliminary analyses comparing Landsat estimates to lidar measurements at 30-m resolution
632 were not appreciably different than those reported here, although there was a small
633 reduction of correlation believed to be due to spatial misregistration of Landsat data.

634 Uncertainty metrics were based on average differences between paired model and
635 reference (or training) values (Willmott, 1982), quantified by Mean Bias Error (MBE), Mean
636 Absolute Error (MAE), and Root-Mean-Squared Error (RMSE):

637

638
$$\text{MBE} = \sum_{i=1}^{n} \frac{M_i - R_i}{n} \tag{10}$$

639

640
$$MAE = \sum_{i=1}^{n} \frac{|M_i - R_i|}{n} \tag{11}$$

641

642
$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{n}(M_i - R_i)^2}{n}} \tag{12}$$

643

644 where M_i and R_i are estimated and reference tree cover values at a location *i* in a sample of
645 size *n*.

646 After modeling the relationship between M and R by linear regression, their (squared)
647 difference was disaggregated into systematic error (MSE_S) and unsystematic error (MSE_U)
648 based on the modeled linear relationship (Willmott 1982):

649

650
$$MSE_S = \sum_{i=1}^{n} \frac{\left(\widehat{M_i} - R_i\right)^2}{n} \tag{13}$$

651

652
$$MSE_U = \sum_{i=1}^{n} \frac{\left(M_i - \widehat{M_i}\right)^2}{n} \tag{14}$$
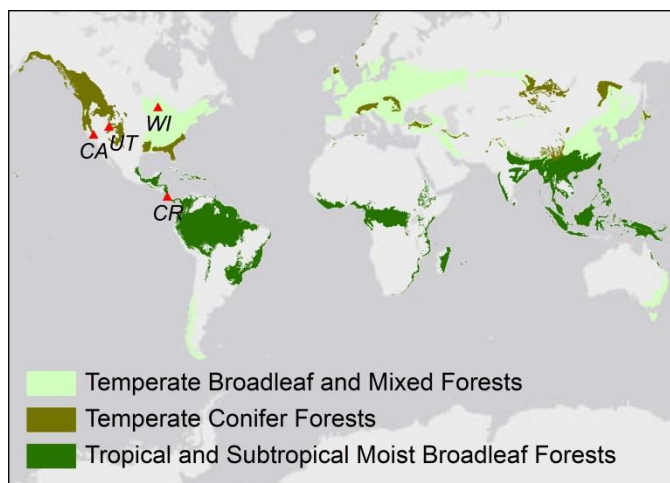

653

21

654 where $\widehat{M_i}$ is the cover value predicted by the modeled relationship (Willmott 1982).
655 Accuracy is thus quantified by the difference between the trend of model over reference
656 cover, and precision is quantified by the variation surrounding that trend. MSE_s and MSE_U
657 sum to Mean-Squared Error (MSE), and therefore:

658

659
$$RMSE = \sqrt{MSE_s + MSE_u}$$
(15)

660

661 (Willmott 1982). To maintain consistency, we report the square roots of MSE_s and MSE_U, i.e.,
662 $RMSE_s$ and $RMSE_U$, in units of percent cover.

3.1.2.3.2 Reference data

664 For comparison to the 2005-epoch estimates, small-footprint, discrete-return lidar
665 measurements were collected at four sites in a range of biomes (Figure 6): (1) La Selva
666 Biological Station and its vicinity, Costa Rica (CR) in 2006; (2) the Wasatch Front in central
667 Utah (UT), USA in 2008; (3) the Sierra National Forest in northern California (CA), USA in
668 2008; and (4) the Chequamegon-Nicolet National Forest, Wisconsin (WI), USA in 2005.

Figure 6. Distribution of lidar-based reference sites, overlaid on global biomes (Olson 2001). Only the major habitat types intersecting reference sites are shown.

673 The Costa Rica site is dominated by tropical moist broadleaf evergreen forest surrounded by
674 livestock pastures. The Utah site is an ecotone of temperate evergreen needle-leaf conifer
675 forest, deciduous broadleaved shrubland, and annual grasses. The California site is
676 dominated by tall, mixed-species temperate evergreen conifer forests of varying cover. The
677 Wisconsin site is dominated by a mixture of temperate deciduous broadleaf hardwood and
678 coniferous needle-leaf tree species with significant coverage of herbaceous agriculture,
679 including corn. All lidar measurements were acquired during the growing season of each
680 respective site, with mean point densities > 1 return/m^2. The Costa Rica dataset, collected in
681 2006, is described by Kellner et al. (2009), and the Wisconsin dataset is described by Cook et

682 al. (2009). Figure 7 shows an example of the 3-dimensional distribution of lidar
683 measurements in the California site. All sites were assessed visually for obvious changes in
684 cover between data acquisitions; in the WI dataset, obvious cover changes due to forest
685 harvesting between Landsat and lidar acquisitions (totaling 21 pixels) were delineated
686 manually and removed.

687

688 **Figure 7. Three-dimensional distribution of a 250x250-m subset of the lidar measurements from the**
689 **California reference site in nadir (left) and oblique (right) perspectives. Data points, which were sampled**
690 **with intensity of approximately 13 points/m^2, are classified by height into tree (pink) and non-tree (yellow)**
691 **classes. The red box in the upper-right corner shows the area of one 30-m Landsat pixel.**

692

693 Tree cover (C) was calculated from lidar returns by dividing the number of returns above a
694 criterion height by the total number of returns within a 10-m radius:

695

696
$$C = \frac{n_h}{n} \qquad\qquad (16)$$

697 where n is the number of returns and n_h is the number of returns above the specified height
698 (h) (Korhonen et al. 2011). In accordance with the International Geosphere-Biosphere
699 definition of forests, we specified the criterion n_h = 5 meters. Following calculation of tree
700 cover at 10-m resolution, rasters were aggregated to 250-m resolution by averaging the
701 values within the extent of each 250-m pixel. In pixels with steep underlying terrain (as
702 might be likely especially in CA and UT), the varying ground elevation in large pixels can
703 cause spurious detection of tree cover as lidar returns above 5-m height; first computing
704 cover in small, 10-m pixels and then aggregating to 250-m pixels avoided this possibility. Also
705 note that Relative Height (i.e., RH100) and other waveform-based metrics (Hyde et al. 2005,
706 Dubayah et al. 2010) were not used; only height of the (discrete-return) lidar posts was used
707 to calculate canopy height.

23

708 ### 3.1.2.3.3 Results

709 *3.1.2.3.3.1 Consistency of Landsat- and MODIS-based (VCF) tree cover estimates*

710 The relationship between Landsat estimates of tree cover and the MODIS data on which
711 they were based was very strongly linear, near parity, and consistent among biomes (Figure
712 8,

713 Table 5, Table 6). Relative to the MODIS estimates, Landsat estimates exhibited MBE of -6%,
714 MAE of 8%, and RMSE of 10% cover (

715 Table 5) in the biome samples of 2005 data. The modeled linear relationship explained 88%
716 of the variation between the two datasets, and RMSE was equally partitioned between
717 systematic and random components, with both $RMSE_S$ and $RMSE_U$ equaling approximately
718 7% cover (Table 7). Although significantly different from zero, the intercept of the linear
719 relationship was relatively small (4.5%).

720 The global Landsat-MODIS VCF comparison for 2000 and 2005 epochs corroborated the
721 aggregated site-specific results, with little difference between epochs (Figure 9). Paired
722 Landsat- and MODIS-based estimates were distributed predominantly along the 1:1 line,
723 with a slight under-estimation of Landsat- relative to MODIS-derived values of cover. Errors
724 were slightly greater in the 2005 than in the 2000 data (RMSE = 8.9% in 2000; RMSE = 11.9%
725 in 2005), and the greatest differences were confined largely to the humid tropics, suggesting
726 their origin might lie in the effects of remnant clouds in the Landsat images. The 2000 GLS
727 "epoch" of image collection was before the 2003 failure of the Scan-Line Corrector (SLC) of
728 the ETM+ instrument, and so the quality of the GLS 2000 dataset likely benefitted from a
729 greater selection of high-quality images from which to choose cloud-free data.

3.1.2.3.3.2   Accuracy of Landsat-based tree cover estimates relative to lidar reference
769   *data*
770   Across the four sampled biomes, the correspondence of Landsat-based estimates of tree
771   cover to reference lidar measurements was similar to the relationship between MODIS-
772   based estimates and lidar-based measurements (Figure 10). Across the biomes, RMSE of
773   Landsat estimates relative to lidar-measured cover was 17%, with MAE of 15% and MBE of -
774   11% cover (Table 6). However, the overall linear relationship between Landsat estimates
775   and lidar measurements was stronger (R^2 = 0.81) than that of MODIS estimates relative to
776   lidar measurements (R^2 = 0.71). This strong linear trend resulted in a greater dominance of
777   systematic ($RMSE_s$ = 15%) over unsystematic, or random noise ($RMSE_U$ =9%) in the Landsat
778   estimates compared to MODIS, suggesting a greater potential for empirical calibration of
779   Landsat estimates than is possible for the MODIS dataset. Although still present, saturation
780   of Landsat estimates relative to lidar measurements was reduced slightly compared to the
781   saturation seen in MODIS-based estimates.

782

783

27

Global Land Cover Facility
www.landcover.org

787

Landsat estimates reproduced the spatial pattern of tree cover in most sites with greater
fidelity than did MODIS estimates (Figure 10). The exception to this was the UT site, where
there was no clear correspondence between either Landsat or MODIS estimates and the
lidar measurements. Another artifact shared in both the Landsat and MODIS data was the
slight compression of the actual frequency distribution of values, such that there were more
intermediate values and correspondingly fewer values near the extremes of cover (i.e., 0 and
100%). It should be stressed, however, that even considering the minor artifacts, Landsat
estimates resolved greater spatial variation in tree cover than did the relatively coarse
MODIS estimates.

3.1.3 Forest cover and change

3.1.3.1 Definitions
Based on the global land cover classification system developed by the International
Geosphere Biosphere Programme (IGBP) (Belward & Loveland 1996), forest is defined as a
minimum area of land of 0.27 hectares with ≥30% tree cover—i.e., as land *cover*, as opposed
to land *use* (Sexton et al., 2016; Townshend et al., 2012). Only net forest/non-forest type-
conversion changes were included in the fine-resolution FCC ESDR products. We defined
"forest gain" as categorical change from non-forest to forest and "forest loss" as change
from forest to non-forest. Stasis of forest or non-forest classification in a pixel over a period
was defined respectively as "persistent forest" and "persistent non-forest".

3.1.3.2 Algorithms

3.1.3.2.1 Forest cover and change from 2000-2005
The following algorithm and its results have been peer-reviewed and are described by
Sexton et al. (2015).

3.1.3.2.1.1 Defining forest cover in terms of tree cover
"Forest" is defined as a class of land cover wherein tree (-canopy) cover, c, exceeds a
predefined threshold value, c^*. The probability of belonging to "forest", $p(F)$, is therefore the
probability of c exceeding the threshold c^* (Figure 11)—i.e., the integral of the density
function of c above c^*:

$$p(F) \stackrel{\text{def}}{=} p(c > c^*) = \int_{c^*}^{100} p(c)dc. \tag{17}$$

Complementarily, the probability of membership in non-forest is simply 1-$p(F)$.

In any location i, tree cover c_i is estimated by a model f of remotely sensed variables $\boldsymbol{X}$
(Hansen et al. 2003, Homer et al. 2004, Sexton et al. 2013b):

28

823     $c_i = f(\boldsymbol{X}; \beta) + \varepsilon_i,$ (18)

824

825   where β is a set of empirically estimated parameters, and ε is residual error.

826

827

828   **Figure 11. Estimation uncertainty of tree and forest cover within a pixel, modeled as a normal probability**
829   **density function of tree cover, with probability of forest (shaded) and non-forest (unshaded) defined relative**
830   **to a threshold of tree cover, c*.**
831

832   Given a joint sample of locations i = [1,2,…n] with coincident true and estimated values of a

833   continuous variable such as tree cover (c_i, $\hat{c}_i$), error may be quantified as the Root-Mean-

834   Square Error (RMSE), which for large samples approximates the standard deviation of

835   estimates of the true value of cover:

836     $\sigma_\varepsilon = \sqrt{\dfrac{\sum_i (c_i - \hat{c}_i)^2}{n-1}}.$ (19)

837

838   Thus, given c_i, and an estimator (e.g., linear regression) producing estimate $\hat{c}_i$ and root-

839   mean-square error $\sigma_i = \sigma$, a Normal probability distribution of possible values of c_i may be

840   assumed (Snedecor and Cochran 1989, Hastie et al. 2001, Clark 2007):

841

842     $p(c_i) \stackrel{\text{def}}{=} N(\hat{c}_i, \sigma^2) = \dfrac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(c_i - \hat{c}_i)^2}{2\sigma^2}}.$ (20)

843

844   Given paired estimates of cover and its RMSE, this model provides a probability density
845   function of tree cover $p(c)$ (Eqn. 13) and therefore the probability of identifying forest for
846   each pixel i (Eqn. 10).

847   *3.1.3.2.1.2   Change detection based on bi-temporal class probabilities*
848   Given the probability of detecting forest in a location i = (x,y) at each of two times t, four
849   dynamic classes (D) are possible: stable forest (FF), stable non-forest (NN), forest gain (NF),
850   and forest loss (FN). Calculating the probability of each of these dynamics at that location
851   simply requires calculating the following joint probabilities:

852

853    $$p(FF)_i = p\big(F_{i,1}, F_{i,2}\big) = p\big(F_{i,1}\big) \times p\big(F_{i,2}\big) \tag{21}$$

854    $$p(NN)_i = p(N_{i,1}, N_{i,2}) = \Big(1 - p\big(F_{i,1}\big)\Big) \times \Big(1 - p\big(F_{i,2}\big)\Big) \tag{22}$$

855    $$p(NF)_i = p\big(N_{i,1}, F_{i,2}\big) = \Big(1 - p\big(F_{i,1}\big)\Big) \times p\big(F_{i,2}\big) \tag{23}$$

856    $$p(FN)_i = p\big(F_{i,1}, N_{i,2}\big) = p\big(F_{i,1}\big) \times \Big(1 - p\big(F_{i,2}\big)\Big) \tag{24}$$

857   where subscripts denote observation times (Figure 12). In practice, the model of error is
858   approximate, and so carets (^) denote that the resulting values are estimates. These joint
859   probabilities sum to unity at each location i, and because they are merely transformations of
860   the original cover and error values in every pixel, they may be mapped geographically
861   without gain or loss of information from those estimates. In order to produce a categorical
862   map of change classes, each pixel may be assigned either the most probable class at i, or
863   some other criterion of probability may be set (e.g., $p \geq 0.9$) to filter detection based on
864   certainty of the tree-cover and derived forest-cover and -change estimates.

Global Land Cover Facility
www.landcover.org

Figure 12. Categorical (forest) change detection based on probabilistic fields of tree cover at two times, t1 and t2.

3.1.3.2.2　Forest cover and change from 1990-2000

The following algorithm and its results have been peer-reviewed and are described by Kim et al. (2014).

3.1.3.2.2.1　*Forest-cover retrieval using stable pixels*

We inferred forest cover in 1990 and change from 1990 to 2000 using a signature-extension approach based on stable pixels hindcast from 2000 and 2005 epochs (Figure 13). For the purpose of large-area mapping, extrapolation of models beyond the immediate temporal and spatial domain in which they were trained has been explored by many researchers (Sexton et al. 2013b; Gray and Song 2013). Termed as "generalization" or "signature extension", this approach has been successfully applied for the classification of forest cover (Pax-Lenney et al. 2001) and change (Woodcock et al. 2001) using Landsat data. This approach also has been implemented by deriving training data from one date and using it to train a classifier on a different image from the same path/row scene but different acquisition date (Pax-Lenney et al. 2001). Complementary to the traditional signature extension method, Gray and Song (2013) combined a procedure to identify stable pixels to deal with irregular time-series images. This approach has been found to be effective for the automated classification of large areas, especially when there are actual changes in class spectral signatures from phenological variability, atmospheric differences, or land cover changes (Fortier et al. 2011, Gray and Song 2013).

31

Global Land Cover Facility
www.landcover.org

888

Figure 13. Hind-cast training and classification procedure to retrieve historical forest cover estimates. SR =
surface reflectance, C = cover, t1 ≈ 1990, and tn≈ 2000 or 20005.

3.1.3.2.2.2   Reference forest/non-forest data

Persistent forest (F) and non-forest pixels (N) were sampled from forest-cover change maps
between 2000 and 2005 GLS epochs and then filtered so that only "stable" pixels—i.e., those
whose class did not change between 1990 and 2000 epochs—were retained for analysis. The
details of the filtering process are presented below.

For each WRS-2 scene, an annual rate of forest-cover (F) change, $\frac{dF}{dt}$, and an annual rate of
non-forest-cover (N) change, $\frac{dN}{dt}$, were calculated as:

$$\frac{dF}{dt} = \frac{|F_{t2} - F_{t1}|}{t2-t1} \tag{25}$$

$$\frac{dN}{dt} = \frac{|N_{t2} - N_{t1}|}{t2-t1} \tag{26}$$

where F and N are the percentage of forest and non-forest pixels, respectively, and t_1 and t_2
were respectively the acquisition years of the Landsat images for 2000 and 2005 GLS epochs.

The spectral difference (ΔSR) - quantified as the Euclidean distance between two pixels over
time in the spectral domain– was calculated for 1990-2000 (ΔSR$_1$) and 2000-2005 (ΔSR$_2$). To
minimize impact from accelerating or decelerating rates of forest-cover change between
two periods, a parameter α was defined as the ratio of the sums of spectral difference of all
persistent pixels and was calculated as:

$$α = ΣΔSR_1/ ΣΔSR_2, \tag{27}$$

Given the large number of available pixels within the overlapping portion of two Landsat
images within the same WRS-2 scene, α was doubled to increase the selectivity of filtering

32

911 for stable pixels. A percentage of forest equaling α x 2 x 100 $\times \frac{dF}{dt}$ and non-forest pixels

912 equaling α x 2 x 100 $\times \frac{dN}{dt}$ were thus removed per year of difference between 1990- and

913 2000-epoch images in the order of spectral difference (ΔSR). Limiting the sample to pixels

914 that were stable from 2000 to 2005 minimized inclusion of erroneous data, and filtering the

915 most spectrally different pixels from 1990 to the later epochs removed the pixels most likely

916 to have changed over that period.

917 *3.1.3.2.2.3   Forest-cover classification*

918 Using the sample of stable-pixel locations, a forest/non-forest reference sample was

919 extracted from forest-cover maps in 2000 and 2005. This sample was then filtered to

920 maximize certainty and minimize change between observation periods (Figure 13).

921 Forest cover in circa-1990 was retrieved by a classification-tree algorithm. The probability of

922 forest cover, p(F), in each pixel *i* at time *t* ≈ 1990 was estimated by a conditional relationship

923 (*g*) to remotely sensed covariates (X):

924 $$\hat{p}(F)_{i,t} = g(X_{i,t}), \tag{28}$$

925 where X is a vector of surface reflectance and temperature estimates; subscripts *i* and *t*

926 denote the pixel's location in space, indexed by pixel, and time indexed by year. The relation

927 *g* was parameterized using the C 5.0 ™ classification-tree software (Quinlan 1986), trained

928 on a sample of pixels within each Landsat image; the model was thus fit locally within each

929 Landsat World Reference System 2 (WRS-2) scene. Reflectance and temperature covariates

930 were acquired from the 1990-epoch Global Land Survey collection of Landsat images

931 (Gutman et al. 2008) and other Landsat images selected from the USGS archive, each of

932 which was atmospherically corrected to surface reflectance and converted to radiant

933 temperature by the LEDAPS implementation of the 6S radiative transfer algorithm (Masek et

934 al. 2006b). Whereas retrievals from within the period of overlap between the Landsat-5,

935 Landsat-7, and MODIS eras may be based on general—even global—models based on

936 phenological metrics that require dense image samples within each year (e.g., Hansen et al.

937 2013), this local fitting instead maximizes use of the single-image coverage characteristic of

938 much of the history of Earth observation. Use of atmospherically corrected surface

939 reflectance fulfills the conditions for signature extension in space (Woodcock et al. 2001,

940 Pax-Lenney et al. 2001).

941 Decision trees and other empirical classifiers are sensitive to bias in training samples relative

942 to class proportions within their population of inference (Borak 1999, Carpenter et al. 1999,

943 Woodcock et al. 2001, Sexton et al., 2013c) and to uncertainty in the training data set

944 (McIver 2002, Strahler 1980). To minimize these effects, we maintained a large sample with

945 representative class proportions by removing a small, but equal fraction of the least stable

946 pixels from each class while maintaining the class proportions from reference epoch to

947 training sample. Further, we weighted each pixel's contribution to the classifier's

948 parameterization based on the pixel's classification certainty in the reference data. A weight

949 *w* was adopted for each pixel as the classification probability of the estimate (p_{max}) of forest-

950 or non-forest cover (C) from the 2000-epoch dataset:

951 $$W_i = p_{max}(C_i). \tag{29}$$

952 The weights were then applied to adjust the objective (i.e., purity) function maximized by
953 the iterative binary recursion algorithm employed by C5.0™ (Quinlan 1986).

954 *3.1.3.2.2.4 Forest-cover change*
955 Classification trees estimate the probability *p(C)* of each class in each pixel as a conditional
956 relative frequency. Given C = "F" (i.e., "forest"), each pixel was labeled either "forest" or
957 "non-forest" based on *p(F)*:

958 $$F \stackrel{\text{def}}{=} p(F) \geq 0.5 \tag{30}$$

959 $$N \stackrel{\text{def}}{=} p(F) < 0.5 \tag{31}$$

960 Forest-cover change between 1990 and 2000 epochs was detected given the joint
961 probabilities in 1990 and 2000 epochs (Sexton et al. 2015):

962 $$p(FF_i) = p(F_{it_1}) \times p(F_{it_2}) \tag{32}$$

963 $$p(NN_i) = \left(1 - p(F_{it_1})\right) \times \left(1 - p(F_{it_2})\right) \tag{33}$$

964 $$p(NF_i) = \left(1 - p(F_{it_1})\right) \times p(F_{it_2}) \tag{34}$$

965 $$p(FN_i) = p(F_{it_1}) \times \left(1 - p(F_{it_2})\right) \tag{35}$$

966 That is, given the probability of forest P(F) vs. non-forest P(N) in a pixel *i* in the 1990-epoch
967 (t_1) and 2000-epoch (t_2), four classes were derived: stable forest (FF), stable non-forest (NN),
968 forest gain (NF), and forest loss (FN). A categorical map of change classes was then produced
969 by assigning each pixel the class with the highest probability.

3.1.3.2.3 Post-processing

971 *3.1.3.2.3.1 Hedge rule*
972 In the forest cover change products, the forest dynamics (i.e., forest loss and forest gain)
973 between two periods were determined by checking the joint probabilities of forest and
974 nonforest estimated for each of the dates (Kim et al., 2014; Sexton et al., 2015). Dynamic
975 classes are more difficult to detect than stable classes, and a criterion is applied to filter the
976 detected change estimates (Kim et al., 2014; Sexton et al., 2015). As an example, Figure 14
977 presents the accuracies for forest loss and gain between 2000 and 2005 calculated with
978 criterions increased from 0.1 to 0.9 at 0.1 intervals. The global overall accuracy of the forest
979 cover change data is insensitive to the changing criterions because areas of forest change
980 are small fractions of global land area, but the criterion has a significant impact to the
981 accuracy of the estimates of the forest dynamics. Higher criterion rules out less certain
982 changes but also leads to high omission errors. On the contrary, lower criterion reduces
983 omission errors, but introduces higher chance of commission errors.

984 According to the investigation presented in Figure 14, commission and omission errors
985 reached the closest point when the criterion is near 0.6 for both forest loss and forest gain.

986　The threshold 0.6 was, therefore, applied to the production of the forest cover change
987　datasets to produce unbalanced estimations of the global forest dynamics.

988

989
990　**Figure 14 Overall and user' and producer's accuracies for forest loss (A) and gain (B) between 2000 and**
991　**2005 estimated with criterions increased from 0.1 to 0.9 at 0.1 intervals.**
992

993　*3.1.3.2.3.2　Minimum Mapping Unit*
994　A minimum mapping unit (MMU) was applied to comply with the forest definition and also
995　to minimize erroneous detection of change due to spatial misregistration of Landsat images.
996　Raster polygons smaller than the threshold MMU (0.27 hectare, or 3 pixels) were replaced
997　by the class of the largest neighboring polygon. An eight-neighbor rule was used to delineate
998　patches, which includes diagonally connected neighbors.

999　***3.1.3.3　Validation***

1000　3.1.3.3.1　Methods

1001　*3.1.3.3.1.1　Sampling design*
1002　Accuracy assessment employed a two-stage, stratified sampling design (Cochran,
1003　1977; Sannier et al., 2014; Särndal et al., 1992; Stehman, 1999; Stehman & Czaplewski,
1004　1998). To increase the representation of rare classes, reference data were sampled across
1005　the global land area in two stages, first selecting Landsat WRS-2 tiles within predefined
1006　global strata and then sampling pixels within each selected tile. The spatial location of
1007　sample points was held constant for all time periods.

1008　*3.1.3.3.1.1.1　Biome definition*
1009　Biome-level stratification was based on the 16 major habitat types delineated by the
1010　Nature Conservancy (TNC) Terrestrial Ecoregions of the World dataset (TNC, 2012).
1011　Excluding deserts and xeric shrublands, inland water, and rock & ice, we merged the major
1012　habitat types into eight forest and non-forest biomes (Table 8). Among the 7,277 WRS-2 tiles
1013　in the 8 biomes, the 5,294 tiles completely contained within any biome were assigned to
1014　their respective biomes, and tiles spanning biome boundaries (including land/ocean

Global Land Cover Facility
www.landcover.org

1015   boundaries) were excluded. This reduced the land area for each of the 8 biomes available

1016   for sampling by 18.7 - 58.2% of each biome (Table 8).

1017

Global Land Cover Facility
www.landcover.org

Table 8. Reclassification of TNC major habitat types (TNC, 2012) into biome strata. The land area for each biome is reported in "Land area (km²)" column, and the percentage of that area reduced by excluding tiles spanning boundaries is reported in "Spanning biome WRS-2 tiles (%)" column. The percentage of the remained area after the "spanning biome" exclusion that further reduced by excluding edge pixels is reported in the "Edge pixels (%)" column.

| Biome strata	TNC biomes	Land area (km²)	Percentage of area reduced	
			Spanning biome WRS-2 tiles (%)	Edge pixels (%)
Tropical Evergreen Forests	Tropical and Subtropical Moist Broadleaf Forests Mangroves Tropical and Subtropical Coniferous Forests	16,608,638	25.2	9.7
Tropical Deciduous Forests	Tropical and Subtropical Dry Broadleaf Forests	6,780,454	18.7	8.4
Tropical Non-forest	Tropical and Subtropical Grasslands, Savannas and Shrublands Flooded Grasslands and Savannas (23°S - 23°N) Montane Grasslands and Shrublands (23°S - 23°N)	15,296,731	28.0	5.5
Temperate Evergreen Forests	Temperate Conifer Forests	3,843,538	50.9	13.2
Temperate Deciduous Forests	Temperate Broadleaf and Mixed Forests Mediterranean Forests, Woodlands, and Scrub	14,013,894	29.1	9.4
Temperate Non-forest	Temperate Grasslands, Savannas and Shrublands Flooded Grasslands and Savannas (23°S - 23°N) Montane Grasslands and Shrublands (23°S - 23°N)	2,918,100	58.2	2.0
Boreal Forests	Boreal Forests/Taiga	20,381,706	24.9	12.3
Boreal Non-forest	Tundra	21,484,150	21.1	3.8
[Excluded]	Deserts and Xeric Shrublands Inland Water			

1023

3.1.3.3.1.1.2   Tile selection

1025   Sampling within biomes focused on WRS-2 tiles exhibiting high rates of vegetation
1026 change, detected using the Training Data Automation and Support Vector Machines (TDA-
1027 SVM) change-detection algorithm (Huang et al., 2008). The median vegetation-change rate
1028 for each biome was then used as the threshold for discriminating high- and low-change
1029 strata for that biome. Within each biome, eight tiles were then randomly selected in the

37

1030 high-change stratum and four tiles were randomly selected in the low-change stratum
1031 (Figure 14).

1032   The inclusion probability, $p(T|G)$, of each WRS-2 tile, T, in each biome, G, was
1033 calculated as:

1034 $$p(T|G) = \frac{n_T}{N_T},$$ (36)

1035 where n_T is the desired number of sampled tiles within the population of the stratum (N_T);
1036 n_T was set to 4 and 8 for low- and high-change strata, respectively. A random number p_1^*
1037 was assigned to each tile, and tiles with $p_1^* < p(T|G)$ were selected as the sample tiles.
1038 Globally, 89 tiles were selected out of the intended 96 because only one tile met the
1039 criterion for the "high-change" stratum in the boreal non-forest biome.

1041 **Figure 14. Biome strata and the collected 89 WRS-2 tiles.**
1042

1043 *3.1.3.3.1.1.3   Point selection*
1044   Following biome-level sampling, each selected tile was divided into 8 strata
1045 representing forest/non-forest status in each of the two periods, 1990-2000 and 2000-2005.
1046 This preliminary forest/non-forest discrimination was again performed by TDA-SVM. All
1047 pixels identified as cloud, shadow, water, or no-data, as well as pixels located at the edge of
1048 two classes, were excluded from the population. This exclusion reduced the available land
1049 area for each of the 8 biomes by 3.8 - 13.2% (Table 8).

1050   The inclusion probability for each stratum was calculated as:

1051 $$p(i|S) = \frac{n_S}{N_S}$$ (37)

1052 where the probability $p(i|S)$ is the ratio of the desired number of pixels (n_s) to the total
1053 number of pixels in the stratum (N_S). As recommended by Congalton (1991) and Olofsson et
1054 al. (2014), n_s was set to 50 for each stratum (S). A random number p_2^* was assigned to each

1055 pixel, and pixels with $p_2^* < p(i|S)$ were selected as the sample points. A total of 27,988

1056 points were thus collected across the globe. Figure 15 shows the selected points in WRS-2

1057 tile p224r078, located at the boundary of Paraguay, Argentina, and Brazil.

1058

1062 **The background image is a false-color (NIR-R-G) Landsat image of July 6, 2000.**

3.1.3.3.1.2 Response design

1064 Forest or non-forest cover in each pixel and each epoch was visually identified by

1065 experienced image analysts using a web-based tool presenting the GLS Landsat image(s)

1066 covering each location, as well as auxiliary information, including: Normalized Difference

1067 Vegetation Index (NDVI) phenology from MODIS, high-resolution satellite imagery and maps

1068 from Google Maps, and geotagged ground photos (Figure 16) (Feng et al., 2012b). The

1069 Landsat images were presented in multiple 3-band combinations—e.g., near infrared (NIR)-

1070 red (R)-green (G), R-G-blue (B), and shortwave infrared (SWIR)-NIR-R. The extent of each

1071 selected 30-m Landsat pixel was extracted in the Universal Transverse Mercator (UTM)

1072 coordinate system and delineated in both the Landsat image and in Google Maps to

1073 facilitate visual comparison. The NDVI profile was derived from the 8-day composited

39

1074   surface reflectance data (MOD09A1; Vermote & Kotchenova, 2008; Vermote et al., 2002)

1075   with nearest-neighbor interpolation, excluding data labeled as cloud or shadow in the

1076   MOD09A1 Quality Assurance (QA) layer (Feng et al., 2012b).

1077   The selected points were randomly distributed among 12 experts for interpretation

1078   (Table 9). Experts visually checked the information provided by the tool and labeled each

1079   point either "forest" or "non-forest" for each of the 3 epochs individually. Points with

1080   Landsat pixels contaminated with cloud or shadow were labeled as "cloud" and "shadow"

1081   respectively. If an expert was unable to identify the cover of a pixel, he or she was instructed

1082   to label it as "unknown" for further investigation.

1083

1084

1085   **Figure 16. The web-based tool for visually identifying forest cover at a selected point (Feng et al. 2012).**
1086

1087

40

1088 **Table 9. Sample sizes of human-interpreted reference data for circa-1990, -2000, and -2005 epochs.**

Type	Number of points		
	1990	**2000**	**2005**
Nonforest	10,657	11,244	11,929
Forest	15,221	15,194	14,448
Unknown	2,025	1,543	1,494
Cloud	9	26	30
Shadow	30	28	28

1089

1090 Over 1,000 collected points were located in each decile of tree cover, with nearly uniform
1091 sample size across the range of tree cover > 10% cover (Figure 17). Of these points, > 90%
1092 were labeled as *forest* or *non-forest* by visual interpretation of TM or ETM+ images in the
1093 1990, 2000, and 2005 epochs, with only 6 % of the points remaining as "unknown". Less
1094 than 1 % of the points across all epochs were interpreted as "cloud" or "shadow". The
1095 distribution of the unknown points in the 2000 epoch revealed that these difficult points
1096 were rare (< 4 %) in areas of low or high tree-canopy cover but were much more frequent in
1097 areas with 5 – 35 % tree cover (Figure 18).

1098

1105

1106 *3.1.3.3.1.3   Validation metrics*

1107   Based on the independent reference sample, the labeled points were used to
1108 quantify the accuracy of the global forest-cover and -change layers using validation metrics
1109 weighted by area (Card, 1982; Congalton, 1991; Stehman & Czaplewski, 1998; Stehman,
1110 2014). For each reference datum, *i,* the agreement between estimated and reference cover
1111 or change, *y*, was defined:

1112 $$y_i = \begin{cases} 1 & \text{if } \hat{c}_i = c_i \\ 0 & \text{if } \hat{c}_i \neq c_i \end{cases}.$$ (38)

1113 Weights were applied to the data to remove the effect of disproportional sampling, by
1114 standardizing the inclusion probability of each observation proportional to the area of each
1115 stratum (Sexton et al., 2013b). Each point's weight, w_i, was calculated as the inverse of the
1116 joint standardized probability of its selection at the tile- and pixel-sampling stages:

1117 $$w_i = \frac{P(i|S)}{p(i|S)} \frac{P(T|G)}{p(T|G)} = \left(\frac{n_S}{N_S} \div \frac{n_i}{N_i} \right) \left(\frac{n_G}{N_G} \div \frac{n_T}{N_T} \right) \cos(\varphi_i),$$ (39)

1118 where $P(i|S)$ is the inclusion probability of the desired number of pixels (n_s) to be randomly
1119 selected from the number of pixels in the Landsat scene (N_S), and $P(T|G)$ is the probability
1120 of the desired number of Landsat tiles (n_g) selected from the total number of Landsat scenes
1121 (N_g) located inside the corresponding biome. Adjusting the weight by the cosine of the
1122 pixel's latitude (φ) corrects the sampling bias due to the increasing density of WRS-2 tiles
1123 with latitude.

1124   Overall accuracy (*OA*) was calculated as the weighted number of points showing
1125 agreement between the estimated and the reference (i.e., human-interpreted) class—i.e.,

elements of the diagonal of the confusion matrix—divided by the weighed total number of points (n_a):

$$OA = \left.\sum_{i=1}^{n_a} y_i \times w_i \middle/ \sum_{i=1}^{n_a} w_i\right. \quad . \tag{40}$$

The conditional probability of the estimate given the reference (i.e., human-interpreted) class, $P(c|\hat{c})$ (i.e., User's Accuracy, UA) and the conditional probability of the reference class given the estimate $P(\hat{c}|c)$ (i.e., Producer's accuracy, PA) were calculated as:

$$CE_c = 1\text{-}UA_c = 1\text{-}\left.\sum_{i=1}^{n_{\hat{c}}} y_i \times w_i \middle/ \sum_{i=1}^{n_{\hat{c}}} w_i\right. \tag{41}$$

$$OE_c = 1\text{-}PA_c = 1\text{-}\left.\sum_{i=1}^{n_c} y_i \times w_i \middle/ \sum_{i=1}^{n_c} w_i\right. , \tag{42}$$

where $n_{\hat{c}}$ were the points identified as type *c* (e.g., forest, non-forest, forest gain, or forest loss) by the GLCF layers, and n_c were the points identified as type *c* by the reference (Stehman, 2014). The inverse of $P(c|\hat{c})$ and $P(\hat{c}|c)$ were interpreted as errors of commission and omission respectively.

3.1.3.3.1.4 Validation metrics
The variance of the accuracy metrics is described below. The points in each forest/non-forest status stratum were randomly selected. Hence, the variance of the *OA* for the stratum and the *UA* and *PA* of class *c* (i.e., forest and non-forest for forest cover; FF, FN, NF, and NN for forest-cover change) in the stratum were calculated following (Congalton & Green 2010, p116-119; Olofsson et al. 2014):

$$v\left(\widehat{OA}\right) = \frac{1}{\sum_{i=1}^{n} n_{+i}^2} \sum_{i=1}^{n} n_{+i}^2 \widehat{UA}_i \frac{(1-\widehat{UA}_i)}{n_{i+}-1} \tag{43}$$

$$v\left(\widehat{UA}_c\right) = \widehat{UA}_c \frac{(1-\widehat{UA}_c)}{n_{c+}-1} \tag{44}$$

$$v\left(\widehat{PA}_c\right) = \frac{1}{\sum_{k=1}^{n} \frac{n_{+k}}{n_{k+}} n_{kc}} \left[\frac{n_{+c}^2 (1-\widehat{PA}_c)^2 \widehat{UA}_c (1-\widehat{UA}_c)}{n_{c+}-1} + \widehat{PA}_c^2 \sum_{i \neq c}^{n} \frac{n_{+i}^2 \frac{n_{ic}}{n_{i+}}\left(1-\frac{n_{ic}}{n_{i+}}\right)}{(n_{i+}-1)}\right], \tag{45}$$

where n_{ij} was the number of points in the error matrix at cell (*i*, *j*), and n_{i+} and n_{+j} were respectively the summaries of row (*i*) and columns (*j*) in the matrix.

The estimated variances ($v(\hat{\theta})$) for the accuracy metrics (i.e., *OA*, *UA*, and *PA*) of the globe and each biome were calculated following (Cochran, 1977):

$$v(\hat{\theta}) = \sum_{k=1}^{n_G} \left(\frac{A_k}{\sum_{l=1}^{n_G} A_l}\right)^2 \left[\frac{1}{n_G} \sum_{j=1}^{n_T} W_j \left(\hat{\theta}_j - \hat{\bar{\theta}}_j\right)^2 + \sum_{i=1}^{n_j} W_{ij}^2 \, v(\hat{\theta}_{ij})\right] \tag{46}$$

43

Global Land Cover Facility
www.landcover.org

1152   where a biome (*G*) consisted of n_G biome-change strata. Each biome-change stratum (*k*)
1153   covered A_k area and included n_T selected WRS-2 tiles. The weight for each tile (*j*) was
1154   calculated as:

1155 $$W_j = \frac{\cos(\varphi_j)}{\sum_{i=1}^{n_T} \cos(\varphi_i)},$$ (47)

1156   where φ_i is the central latitude of tile (*j*). A tile (*j*) consisted of n_j forest status strata, and the
1157   accuracy for the tile ($\hat{\theta}_j$) was estimated:

1158 $$\hat{\theta}_j = \sum_{i=1}^{n_j} W_{ij}\, \hat{\theta}_{ij},$$ (48)

1159   where W_{ij} was the weight for a forest status stratum (*i*) within tile (*j*):

1160 $$W_{ij} = \frac{N_{ij}}{\sum_{i=1}^{n_j} N_{ij}},$$ (49)

1161   where N_{ij} was the number of pixels in stratum (*i*) of tile (*j*). The mean ($\bar{\hat{\theta}}_j$) of accuracy ($\hat{\theta}_j$)
1162   for tile (j) was calculated:

1163 $$\bar{\hat{\theta}}_j = \sum_{j=1}^{n_T} W_j\, \hat{\theta}_j.$$ (50)
1164

1165   The standard error (SE) of each accuracy metric was calculated as the square root of its
1166   variance:

1167 $$SE(\hat{\theta}) = \sqrt{v(\hat{\theta})}.$$ (51)
1168

1169   3.1.3.3.2   Results

1170   *3.1.3.3.2.1   Accuracies of forest-cover layers*
1171   Accuracy of forest-cover detection was consistently high across all biomes and
1172   epochs, with OA = 91% (SE≈1%) in each of the 1990, 2000, and 2005 layers (Figure 11, Table
1173   10). Commission errors (CE = 1 - P(c|ĉ)) and omission errors (OE = 1 - P(ĉ|c)) were < 10% for
1174   both forest and non-forest classes in all epochs, for which SE < 2.3%. The original,
1175   unadjusted estimates showed a bias toward detection of non-forest, with the forest class
1176   having a higher rate of omission errors (<21%) than commission errors (<3%) and the non-
1177   forest class having a higher rate of commission errors (<13%) than omission errors (<2%) in
1178   all epochs and biomes (Table 11).

1179

Table 10. Percentage accuracies of the 1990, 2000, and 2005 forest-cover layers relative to human-interpreted reference points. The standard error associated with each accuracy is reported in brackets.

Type	1990		2000		2005	
	$P(c|\hat{c})$	$P(\hat{c}|c)$	$P(c|\hat{c})$	$P(\hat{c}|c)$	$P(c|\hat{c})$	$P(\hat{c}|c)$
F	97.2 (1.99)	79.8 (1.05)	98.2 (1.24)	79.9 (1.09)	97.9 (1.15)	79.8 (1.06)
N	87.8 (1.93)	98.5 (1.10)	87.6 (2.28)	99.0 (1.19)	87.9 (2.20)	98.8 (1.44)
OA	90.9 (1.03)		91.1 (0.96)		91.2 (1.01)	

The largest overall accuracies (OA) were found in temperate forest and non-forest, tropical evergreen, and boreal non-forest biomes—each of which had OA > 90% (SE < 5%) (Table 11). OA were slightly lower in boreal forests (83% < OA < 89%); OA of tropical deciduous forest ranged from 80.7% to 84%; and OA of tropical non-forest ranged from 83.2% to 84.1%. Standard errors of OA were lowest (<1.6%) in evergreen forests and temperate nonforest, slightly higher in deciduous and boreal forest (<2.9%), and highest in boreal and tropical nonforest (<5%). Evergreen and boreal forests had the lowest rate of omission error (OE < 21%; SE < 3.5%) for the forest class, followed by deciduous forests (24% < OE < 55%; SE < 9.6%) and non-forest biomes (59% < OE; SE < 7.6%). The non-forest class had low omission error (OE < 10%; SE < 8.5%) in all biomes, and its commission error rate was larger in the forest biomes (≤ 32.3%; SE < 6.3%) than the non-forest biomes (≤ 18.3%; SE < 3.3%).

These estimates of accuracy are likely conservative, given our exclusion of treeless biomes and the uncertainty of reference data generated by identifying forest cover by visual interpretation of satellite images (Montesano et al., 2009; Sexton et al., 2015a). Montesano et al. (2009) found that human experts achieved 18.7% RMSE in visual estimation of tree cover in high-resolution imagery, and Sexton et al. (2015a) found that visual confusion was greatest near the threshold of tree cover used to define forests, especially when interpreting change. To investigate the relation between accuracy and tree cover, OA of forest/non-forest cover in 2000 was plotted over the range of coincident tree cover estimated by the NASA GFC tree-cover dataset (Sexton et al., 2013a). A distinct concavity was evident in the relation, which reached its minimum near the 30% tree-cover threshold used to define forests (Figure 19). The OA was large (> 80%) where tree cover was < 0.1 or > 0.35. Commission and omission errors were also investigated in relation with tree cover (Figure 20). Commission error of the forest class was < 10% except among pixels with tree cover < 0.35, where the commission error was < 20%. Omission error of forest was < 20% in areas with > 0.4 tree cover but increased in areas of sparse tree cover.

3.1.3.3.2.2 Accuracies of forest-change layers

Globally, overall accuracy (OA) of the 1990-2000 forest-change layer equaled 88.1% (SE = 1.19%), and OA = 90.2% (SE = 1.1%) for the 2000-2005 forest-change layer (Table 12). In each period and biome, OA ≥ 78.7% (SE < 5%) (Table 13). The global accuracies and standard errors of stable forest (FF) and stable non-forest (NN) classes were similar respectively to those of the stable forest and non-forest classes in the 1990, 2000, and 2005

45

1216   layers, but the change classes—i.e., forest loss (FN) and forest gain (NF)—had larger error

1217   rates than the static classes in the respective epochs.

1218   Commission and omission errors for forest loss were between 45% and 62% globally,

1219   with SE between 1.72% and 23.48%. Forest-loss was detected most accurately, with errors

1220   dominated by commission, in temperate and tropical evergreen forest biomes (PA ≥ 71.7%;

1221   UA ≥ 49.6%). This was likely due to relatively minimal impact of vegetation phenology on

1222   canopy reflectance in evergreen forests. Whether in temperate or tropical regions, detection

1223   of forest loss was more accurate in evergreen forests than in their deciduous counterparts

1224   (30% ≤ PA < 39%; 36.1% ≤ UA ≤ 50.1%). In non-forest biomes, accuracy of forest-loss

1225   detection was very low and dominated by omissions, but the rarity of forests and their loss

1226   in these biomes made the impact of these errors on overall accuracy small.

1227   Forest gain was consistently the most difficult dynamic to detect, with OE and CE

1228   each > 60% in all epochs (SE < 17%). This was likely due to the long traversal of intermediate

1229   tree cover during canopy recovery from disturbance, compounded by the uncertainty of

1230   human identification of change (Sexton et al. 2015a). Producer's accuracies tended to be

1231   largest in tropical evergreen forests (24.9% ≤ PA ≤ 75.7%), where canopy recovery following

1232   disturbance is fastest, and smallest in non-forest biomes (PA < 19%; UA < 17%), where

1233   recovery is slower and locations spend more time in intermediate ranges of canopy cover.

1234   The effect of tree cover on accuracy was investigated using the 2000-2005 forest-

1235   change layer (Figure 21). Similar to that of the 2000 forest-cover layer, a distinct concavity

1236   was evident in the relationship between overall forest-change accuracy and tree cover, and

1237   accuracy was lowest between 0.2-0.3 tree cover. Commission and omission errors of stable

1238   forest and non-forest in relation to tree cover were similar to those of forest and non-forest

1239   in the static layers (Figure 22). The commission and omission errors were large in areas with

1240   tree cover < 0.35 and decreased to < 60% in areas with tree cover > 0.35. Commission and

1241   omission errors of forest gain were both correlated to tree cover. The omission error was <

1242   45% and commission error was < 70% in areas with 0.3 - 0.6 tree cover but > 50% in high or
1243   low tree cover.

1244 **Table 11 Accuracies of the global forest cover products estimated by biomes. The standard error associated with each accuracy is reported in brackets. The values are presented in**
1245 **percentages.**

| Accuracy	Type		Boreal forest	Boreal non-forest	Temperate deciduous forest	Temperate evergreen forest	Temperate non-forest	Tropical deciduous forest	Tropical evergreen forest	Tropical non-forest

3.1.4 Fragmentation

3.1.4.1 Algorithms

3.1.4.1.1 Forest Edge

Forest edge was mapped as the Euclidean distance from each forest pixel to its nearest non-forest pixel at 90-m resolution. For each 90-m "forest" pixel f, the Euclidean distance was calculated to the nearest "non-forest" pixel f':

$$E_f = \sqrt{(x_f - x_{f'})^2 + (y_f - y_{f'})^2},$$ (52)

where x and y are meters of longitude and latitude in Lambert Azimuth Equal Area projection, respectively. The calculation was not performed in non-forest pixels, and so the resulting map represents only *forest*-edge effects. Non-forest pixels were coded with null values. Because this process takes an (area-weighted) average of all forest pixels within the extent of each 1-km pixel, even 1-km pixels with only one 90-m forest pixel show a distance value. Pixels—especially those with small edge-distances—should not be interpreted as fully forested. Histograms were tallied from these data for each continent and summed globally before coarsening to 1-km resolution via bilinear interpolation.

3.1.4.1.2 Forest-patch area

Forest patches were defined by applying an 8-neighbor rule and a 1-ha minimum mapping unit to the binary forest/nonforest map at 90-m resolution. Each forest patch was then labeled with a unique value, i, and area calculated as the sum of all (forest) pixel's area within i:

$$A_i = \sum_f dx_f \times dy_f; f \in i$$ (53)

where $dx = dy = 90$ m.

To enable computation, the calculation was performed for each continent individually and the results merged; buffers were used to avoid truncation of patch size near continental borders.

##### 3.1.4.1.3 Forest-patch isolation

Isolation of forest patches was calculated as the least edge-to-edge distance from each forest patch to the nearest forest patch:

$$I_i = min\left(\sqrt{(x_i - x_{i'})^2 + (y_i - y_{i'})^2}\right); i \neq i'.$$ (54)

I_i was calculated based on the (x,y) location of pixel centers, and so the metric has a minimum value of 180 m. To enable computation, Eqn (54) was calculated for a random 20% of patches i, but against all patches i'. Quantitative analyses were performed using these data before coarsening to 5-km resolution.

3.2 Data-product access and computation

All of the NASA GFC datasets have been made available via the Global Land Cover Facility (www.landcover.org), via the GLCF Earth Science Data Interface (ESDI) and File Transmission Protocol (FTP). Developed with support from the NASA REaSON program, ESDI is a web-based tool for users to search and download data from GLCF's archive using spatial and non-spatial queries. FTP is used by those who are more familiar with the structure of the GLCF archive, those who want to automate data downloading using scripts, and for those who use GLCF as a read-only "cloud" storage solution.

Figure 23. A user has selected Landsat ETM+ and SRTM dataset for the state of Maryland. The area highlighted in darker red is the Landsat based WRS-2 tiles that intersect the Maryland state boundary.

ESDI's mapping interface uses Java Server Pages (JSP) coupled with MapServer. JSP handles the user clicks for selecting data and selecting the type of query and passes the attributes to MapServer for displaying the data coverage on the map (Figure 23). This is helpful for users to know if their area of interest has data coverage.

3.2.1 Landsat Global Land Survey

Although the entire Landsat archive is now available through the USGS EROS Data Center, a large portion of users prefer optimized data collections such as the Global Land Survey (GLS). The GLS is the result of a partnership between the USGS and NASA in support of the U.S. Climate Change Science Program (CCSP) and the NASA Land-cover and Land-use Change (LCLUC) Program. Building on the existing GeoCover dataset (Tucker, et al, 2004) developed for the 1970's, 1990, and 2000, the GLS was selected to provide wall-to-wall, orthorectified, cloud-free Landsat coverage of Earth's land area at 30-meter resolution in nominal "epochs" of 1975, 1990, 2000, 2005 and 2010.

Figure 24. Over half a petabyte (~534 terabytes) of GLS data distributed.

The GLCF currently houses and distributes the GLS Landsat dataset for 1975, 1990, 2000, 2005 and 2010 epochs. Depending on the epoch, approximately 7–10,000 Landsat scenes have been compiled to cover the global land area (Gutman et al. 2013; Feng et al. 2013). Over 534 terabytes of the GLS collection have been distributed during the NASA MEaSUREs project. This number does not include the additional Landsat data (Channan et. al, 2015) that was downloaded to improve the characterization of tree cover.
3.2.2 Surface Reflectance

The GLCF built the LEDAPS modules on their cluster and started processing the GLS2000 collection in 2009. In processing the GLS collection we identified issues in the data and notified USGS. Upon correction of the data, we downloaded the data, and reprocessed it to SR. On our cluster we were able to process the GLS2000 data in about two weeks. As we added more nodes to the cluster we could ultimately process it in about 4 days. In June of 2011, we launched the first global Landsat based SR product upon the submission of the peer reviewed paper (Feng et. al, 2012) to Remote Sensing of Environment, which was accepted in 2012.

Figure 25. The Landsat-based, Global Land Survey surface reflectance mosaic. Data are available at www.landcover.org.

The product was a success and significantly added to the total volume of data distributed via the GLCF. Roughly 15 terabytes of the GLS-2000 SR dataset were distributed during the first month that the product was available. The subsequent spikes in data distribution were due to either new versions or additional epochs of data being added to the online archive. The large spike in June 2015 likely was due to USGS LPDAAC copying the entire GLCF entire SR archive as part of the MEaSUREs data-archiving process. A total of roughly 192 terabytes of data have been distributed to date.

Figure 26. Volume of the GLS Landsat-based based surface reflectance data product distributed via the GLCF (www.landcover.org).

3.2.2.1 Data Formats and Values

The SR data product was distributed in GeoTIFF file format. Each bands with in a folder were individually compressed and separately made available via FTP.
Science Data Sets	Units	Bit Type	Fill	Valid Range	Scale factor (multiply)
Band1 Surface Reflectance	Reflectance	16-bit signed integer	-9999	-2000,16000	0.0001
Band2 Surface Reflectance	Reflectance	16-bit signed integer	-9999	-2000,16000	0.0001
Band3 Surface Reflectance	Reflectance	16-bit signed integer	-9999	-2000,16000	0.0001
Band4 Surface Reflectance	Reflectance	16-bit signed integer	-9999	-2000,16000	0.0001
Band5 Surface Reflectance	Reflectance	16-bit signed integer	-9999	-2000,16000	0.0001

Band6 TOA Temperature	Celsius	16-bit signed integer	-9999	-7000, 7000	0.01
Atmospheric Opacity of band1		16-bit signed integer	-9999	-2000,16000	0.0001
Landsat SR QA		16-bit signed integer	-1	0, 32767	N/A

Table 14: Values stored in the Landsat SR QA file

Quality Flags	Description
Bit 0	Unused
Bit 1	Data Quality flag (0=Valid data, 1=Invalid data)
Bit 2	Cloud mask (0=clear, 1=cloudy)
Bit 3	Cloud shadow mask
Bit 4	Snow mask
Bit 5	Land mask (0= water, 1=land)
Bit 6-15	Unused

3.2.3 Tree Cover

The tree cover data product, though initially an ancillary layer for generating the forest and forest cover change product, quickly became an important source of information for the user community. The team started generating the product late 2012 and stated distributing the data in early 2013. We have processed GLS 2000, 2005 and 2010 to tree cover for this project. Since there is no MODIS tree cover product for the 1990s, we have not been able to generate tree cover before the year 2000. Further improvement of the tree cover product is ongoing with funding support from NASA Carbon Cycle Science and Land Use Land Cover Change programs.

Figure 27: A total of 29530 gigabytes of Landsat Tree Cover data has been downloaded at GLCF

3.2.3.1 Data Formats and Values

The derived tree cover product was tiled using the WRS-2 two tiling scheme and kept the native projection information from the Landsat tile. Each tree cover data folder has 6 files associated with it; a browse file, preview file, data file, a per pixel uncertainty layer, an index file, and a text file. See the example below:

p015r033_TC_2000: The tree cover data folder is named using the following convention: *p* stands for path, followed by *three digits* which represent the WRS-2 path, then *r* which stands for row followed by the *three digits* which represent the WRS2- row. Between the underscore are two letters (*TC*) which is the short name for the tree cover product, followed by *four digits* which represents the year for which the dataset was generated.

- p015r033_TC_2000.browse.jpg: A jpeg file that allows users to easily visualize the data in the browser without downloading the data.
- p015r033_TC_2000.preview.jpg: A small thumbnail jpeg.
- p015r033_TC_2000.tif.gz: The tree cover data file in GeoTIFF file format.
- p015r033_TC_2000_err.tif.gz: The uncertainty layer, that provides per pixel uncertainty per tile
- p015r033_TC_2000_idx.tif.gz: The data provenance layer which uses numerical values associated in the *_idx.txt file to allow the user to understand how many and which file each pixel was obtained from to create this single tile.
- p015r033_TC_2000_idx.txt: The list of files that were used to generate each tile.

Table 15: Code values stored in the tree cover data file.

Value	Label
0-100	Percent of pixel area covered by tree cover
200	Water
210	Cloud
211	Shadow
220	Filled Value

3.2.4   Forest Cover and Change

Results of the world's first global forest cover and change product (version 0) were presented at the NASA LCLUC meeting in 2012 and were subsequently published (Townshend et. al, 2012).   We made the beta release of the forest cover and change in May 2013 to select user group to assess the data get feedback. Once we received the feedback we improved the product and released version 1 of the product in May of 2014. We are currently distributing the forest cover and change product from 1990 to 2000 and 2000 to 2005.

Figure 28: A total of 3,766 gigabytes of forest cover change data were downloaded

3.2.4.1   *Data Formats and Values*

The derived forest cover product was tiled using the WRS-2 tiling scheme and kept the native resolution information from the tree cover product that was used to generate the forest cover and change product. Each forest cover folder has 4 files associated with it; a browse file, a preview file, the change map file and the change probability file. See example below:

p015r033_FCC_19902000: The forest cover and change data folder is named using the following convention: *p* stands for path, followed by *three digits* which represent the WRS-2 path, then *r* which stands for row followed by the *three digits* which represent the WRS2- row. Between the underscore

are three letters (*FCC*) which is the short name for the tree cover product, followed by *eight digits* which represents the years for which the dataset was generated.

- p015r033_FCC_19902000.browse.jpg: A jpeg file that allows users to easily visualize the data in the browser without downloading the data.
- p015r033_FCC_19902000.preview.jpg: A small thumbnail jpeg.
- p015r033_FCC_19902000_CM.tif.gz: The forest cover and change file in GeoTIFF file format.
- p015r033_FCC_19902000_CP.tif.gz: The forest cover and change probability file.

Table 16: Code values stored in the forest cover and change file.

Value	Label
0	No Data
2	Shadow
3	Cloud
4	Water
11	Persistent Forest
19	Forest Loss
91	Forest Gain
99	Persistent Non-forest

3.2.5 Archival, distribution

All of the data generated in this project was processed at the GLCF on a Linux cluster. Additional Landsat data that was used to improve the tree cover and ultimately the forest cover and change product was downloaded from USGS using the Bulk Data Order web based application. Though the data was initially distributed at GLCF, the data are shall be ultimately housed at LPDAAC. As of now all of the data generate from this project has been transferred to LPDAAC for archival and can be downloaded at http://e4ftl01.cr.usgs.gov/provisional/gfcc/.
